# Compiler Design

# Recap

- Intermediate code generation
  - Expressions
    - Arithmetic
    - Boolean
    - Arrays
  - Statements
    - Assignment
    - Control flow
      - if, if-else, while

# Outline

- Intermediate code generation
  - Declarations
    - Type checking

# Type system

- What is a type in the programming language?

# Type system

- A type is a set of values and operations on those values
- A language's type system specifies which operations are valid for a type
- The aim of type checking is to ensure that operations are used on the variable/expressions of the correct types

# Type system

- Languages of three categories w.r.t type:
  - “untyped”
    - No type checking needs to be done
    - Assembly languages
  - Statically typed
    - All type checking is done at compile time
    - Algol class of languages
    - Also, called strongly typed
  - Dynamically typed
    - Type checking is done at run time
    - Mostly functional languages like Lisp, Scheme etc.

# Type systems

- Static typing
  - Catches most common programming errors at compile time
  - Avoids runtime overhead
- Most code is written using static types languages
- In fact, developers for large/critical system insist that code be strongly type checked at compile time even if language is not strongly typed.

# Type expression

- Type of a language construct is denoted by a type expression
  - It is either a basic type OR
  - it is formed by applying operators called *type constructor* to other type expressions

# Type expression

- **Basic types:**
  - integer, char, float, boolean
- **Constructed type:**
  - array, record, pointers, functions
- **Enumerated type:** (violet, indigo, red)

# Type Constructors

- **Array**: if  $T$  is a type expression then  $\text{array}(I, T)$  is a type expression denoting the type of an array with elements of type  $T$  and index set  $I$

$\text{int } A[10];$

$A$  can have type expression  $\text{array}(0 \dots 9, \text{integer})$

- **Product**: if  $T_1$  and  $T_2$  are type expressions then their Cartesian product  $T_1 * T_2$  is a type expression
  - Pair/tuple

# Type constructors

- **Records**: it applies to a tuple formed from field names and field types. Consider the declaration

```
type student = record
  id: integer;
  name: array [1 .. 15] of char
end;

var s: student;
```

# Type constructors

- **Pointer**: if  $T$  is a type expression then  $\text{pointer}(T)$  is a type expression denoting type **pointer to an object of type  $T$**

# Specifications of a type checker

- Consider a language which consists of a sequence of declarations followed by a single expression

$$P \rightarrow D ; E$$
$$D \rightarrow D ; D \mid \text{id} : T$$
$$T \rightarrow \text{char} \mid \text{integer} \mid T[\text{num}] \mid T^*$$
$$E \rightarrow \text{literal} \mid \text{num} \mid E \% E \mid E [E] \mid *E$$

# Specifications of a type checker ...

- A program generated by this grammar is

```
key : integer;  
key %1999
```

- Assume following:
  - basic types are char, int, etc
  - all arrays start at 0
  - char[256] has type expression  
array(0 .. 255, char)

# Rules for Symbol Table entry

|                                 |   |
|---------------------------------|---|
| $D \rightarrow id : T$          | <code>addtype(id.entry, T.type)</code>                    |
| $T \rightarrow \text{char}$     | <code>T.type = char</code>                                |
| $T \rightarrow \text{integer}$  | <code>T.type = int</code>                                 |
| $T \rightarrow T_1^*$           | <code>T.type = pointer(T<sub>1</sub>.type)</code>         |
| $T \rightarrow T_1[\text{num}]$ | <code>T.type = array(0..num-1, T<sub>1</sub>.type)</code> |

# Type checking for expressions

$E \rightarrow \text{literal}$

$E.\text{type} = \text{char}$

$E \rightarrow \text{num}$

$E.\text{type} = \text{integer}$

$E \rightarrow \text{id}$

$E.\text{type} = \text{lookup}(\text{id}.\text{entry})$

$E \rightarrow E_1 \% E_2$

$E.\text{type} = \text{if } E_1.\text{type} == \text{integer and } E_2.\text{type} == \text{integer}$   
    then integer  
    else type\_error

# Type conversion

- Consider expression like  $x + i$  where  $x$  is of type **real** and  $i$  is of type **integer**
- Internal representations of integers and **reals are different** in a **computer**
  - different machine instructions are used for operations on **integers and reals**
- The compiler has to **convert both** the **operands** to the **same type**
- Language definition specifies what conversions are necessary.

# Type conversion

- Type checker is used to insert conversion operations:

$x + i$

$x + \text{inttoreal}(i)$

- Type conversion is called **implicit/coercion** if done by **compiler**.
- It is limited to the situations where **no information is lost**
- Conversions are **explicit** if **programmer** has to **write something to cause conversion**

# Type checking for expressions

|                                     |  |
|-------------------------------------|--|
| $E \rightarrow \text{num}$          | $E.\text{type} = \text{int}$   |
| $E \rightarrow \text{num.num}$      | $E.\text{type} = \text{real}$  |
| $E \rightarrow \text{id}$           | $E.\text{type} = \text{lookup}(\text{id.entry})$   |
| $E \rightarrow E_1 \text{ op } E_2$ | $E.\text{type} =$<br>if $E_1.\text{type} == \text{int} \ \&\& \ E_2.\text{type} == \text{int}$<br>then $\text{int}$<br>elif $E_1.\text{type} == \text{int} \ \&\& \ E_2.\text{type} ==$<br>$\text{real}$ then $\text{real}$<br>elif $E_1.\text{type} == \text{real} \ \&\& \ E_2.\text{type} == \text{int}$<br>then $\text{real}$<br>elif $E_1.\text{type} == \text{real} \ \&\& \ E_2.\text{type} == \text{real}$<br>then $\text{real}$ |
